ABSTRACT

Neuroendocrine tumours of the gastroenteropancreatic tract (GEP-NETs) comprise a group of very heterogeneous neoplasms, which are considered ‘rare diseases’. Epidemiological studies on the incidence of GEP-NETs worldwide have reported a remarkable increase in the detection of these tumours. In a recent study, based on pathology reports (PALGA) to investigate the incidence of pancreatic and duodenal neuroendocrine tumours in the Netherlands from 1991 until 2009, we also noticed a significant increase in the incidence of these tumours. In particular, the incidence of non-functioning neuroendocrine tumours had significantly increased over this period. Remarkably, a substantial discrepancy was observed between the numbers of neuroendocrine tumours diagnosed in the clinical as opposed to the pathological setting, emphasising that these tumours provide a real diagnostic challenge. To improve the diagnosis of GEP-NETs, we advocate that these complex neoplasms should receive more specialised attention. In this mini-review we provide an overview of the current diagnostic approach to GEP-NETs, and add the recent developments in establishing the diagnosis of these tumours, in order to increase knowledge and awareness of GEP-NETs among clinicians and pathologists. Early detection in order to prevent morbidity from GEP-NETs is advocated.

KEYWORDS

Carcinoid, diagnosis, gastrointestinal, neuroendocrine tumour, pancreas

INTRODUCTION

Gastroenteropancreatic neuroendocrine tumours (GEP-NETs) are considered to be rare, heterogeneous and complex neoplasms. 1 They include the pancreatic (PNETs) and gastrointestinal (GI) neuroendocrine tumours (GI-NETs) or carcinoids, which share their origin of cells from the diffuse neuroendocrine system, but further also show many differences regarding pathogenesis, clinical behaviour and prognostic outcome. 2, 3 Characteristic for GEP-NETs is their ability to produce bioactive substances (table 1). 4 Based on the clinical symptoms and syndrome caused by these peptides, they can be divided into functioning (F-NETs) and non-functioning tumours (NF-NETs). Due to their heterogeneity, GEP-NETs often provide a diagnostic challenge to physicians. Although GEP-NETs are generally more indolent than carcinomas, the majority are malignant, showing aggressive tumour behaviour and presenting with metastases at diagnosis. 1 GEP-NETs can occur sporadically, or as part of a hereditary syndrome such as multiple endocrine neoplasia syndrome type 1 (MEN-1), von-Hippel Lindau disease (vHLD), neurofibromatosis type 1, or tuberous sclerosis. 5 In 2007, a summit meeting on the major clinical, pathological and scientific challenges in the field of GEP-NETs was held to debate on potential solutions. 6 There was consensus between the participants that there is worldwide a substantial lack of knowledge, experience and reliable research concerning GEP-NETs. In line with these observations, we feel that also in our country, GEP-NETs indeed present a relatively unknown and underdeveloped subject with fairly limited knowledge among most physicians. However, since several epidemiological studies...
have shown an increase in the incidence of GEP-NETs worldwide, in combination with the fact that these tumours, when accurately managed, provide a relatively good prognosis for the patients, we feel that it can be worthwhile to increase the awareness of and knowledge among clinicians and pathologists, in order to further increase the early detection and prevent morbidity from GEP-NETs.\(^7\)\(^{-10}\)

In this mini-review, we describe the current diagnostic approach of GEP-NETs, in combination with several common pitfalls and some recent developments, to improve the diagnosis of these tumours. In addition, we provide a diagnostic algorithm to facilitate their diagnostic approach.

## Epidemiology

Based on pathology information from PALGA, the nationwide network and registry of histopathology and cytopathology in the Netherlands, we calculated incidence of GEP-NETs from 2000 until 2008 in the Netherlands.\(^8\)\(^,\)\(^9\)

For both pancreatico-duodenal NETs and GI-NETs a significant increase in incidence over time was noticed (figure 1).

However, these calculated incidence rates are based on pathology information only and therefore might represent an underestimation. In our study, we found that this was approximately 25\%, due to the fact that some patients with clinically diagnosed gastrinomas were not included in the PALGA database, because they had not undergone any surgery, biopsy and/or other pathological evaluation for their tumour.\(^9\) This discrepancy between clinical and pathology incidence of GEP-NETs is an important issue concerning these tumours, which will be discussed later. Nonetheless, this pattern of increasing incidence rates indicates and confirms that GEP-NETs might not be as rare as previously thought. Whether this increase is due to improved detection methods rather than to a true rise in the existence of these tumours is debatable. In that context it is important to note that we observed that 4\% and 14\% of the GI-NETs and pancreaticoduodenal NETs respectively, were found incidentally at autopsy, which indicates that, despite improved detection methods, some GEP-NETs still remain undetected.

## Current Diagnostic Procedure for GEP-NETs

Symptoms of patients with GEP-NETs are in general related to the localisation and hormonal production of the tumour.

Using linear regression, trends in annual incidence rates over 2000 till 2008 were analysed. A statistically significant increase was observed in the overall annual incidence of all GEP-NETs, and GI-NETs and pancreaticoduodenal NETs separately, over the study period.
tumour. Frequently, symptoms are vague and aspecific, although symptoms associated with a clinical syndrome may arise suspicion for a F-PNET, table 1.

Next to standard medical history and physical examination, laboratory analyses are crucial in the diagnosis. To diagnose NETs, chromogranin A (CgA) levels can be determined in plasma/serum, or immunohistochemically. Increased plasma/serum levels of CgA have been reported to correlate with a worse prognosis in these patients. Increased levels of 5-hydroxyindoleacetic acid (5-HIAA, the breakdown product of serotonin) can be determined in a 24-hour urine sample collection, and indicate the presence of a serotonin-producing tumour. Increased levels of hormones such as insulin, indicate the presence of a hormone-secreting functioning PNET. Imaging of GEP-NETs includes endoscopy or gastroscopy, octreoscan, computerised tomography (CT) scan, or magnetic resonance imaging (MRI) scan.

Pathological examination of biopsies or surgical specimens reveals the verification of the neuroendocrine nature of the tumour by immunohistology, for pan-neuroendocrine markers such as keratin, CgA, neuron specific enolase (NSE), synaptophysin, grimelius, and CD56. A proliferation marker (Ki67 or MIB1) must be used to assess the degree of differentiation and proliferation, to grade the tumours according the World Health Organisation (WHO) classification. Tumour characteristics as localisation, size, composition, relationship to anatomic structures, resection margins, and the presence of metastases, should be assessed in order to classify the tumour according to the tumour node metastasis (TNM) staging system.

**PITFALLS IN THE DIAGNOSIS OF GEP-NETS**

One of the major pitfalls in the nomenclature of neuroendocrine tumours is the use of the term ‘carcinoid’. In 1907, Oberndorfer introduced this term for neuroendocrine tumours with a relatively ‘benign’ course.

Increasing knowledge about these tumours, however, led to the conclusion that carcinoids also encompass low-grade and high-grade malignant tumours. Therefore, Soga *et al.* called the term ‘carcinoid’ a ‘misnomer’. In fact, this term has been used for different goals; whereas pathologists label all tumours with neuroendocrine features as a ‘carcinoid’, clinicians use ‘carcinoid’ for serotonin-producing tumours that lead to the carcinoid syndrome. Therefore, Capella *et al.* suggested replacing ‘carcinoid’ by ‘neuroendocrine tumour’ to include all tumours with neuroendocrine features, but also realised that abandoning this term completely would be too confusing, and therefore proposed to utilise it for the specification of a NET with serotonin production or producing any other substance which may lead to the carcinoid syndrome.

As consenus in the use of the GEP-NETs nomenclature is highly desirable, we propose that henceforth 1) the term ‘carcinoid’ should be used solely in the clinical setting, and only for those tumours that lead to the carcinoid syndrome as a result of the hypersecretion of serotonin, prostaglandins, or tachykinins by the tumour, characteristic of symptoms such as flushing, diarrhoea and wheezing; 2) pathologists distinguish the various types of neuroendocrine tumours; neuroendocrine tumours should be defined according to the classification of the WHO, thereby replacing ‘carcinoid’ by ‘neuroendocrine tumour’ for well-differentiated low-grade malignant carcinoids, whereas malignant carcinoids should be defined as ‘neuroendocrine carcinomas’.

Another misunderstanding among pathologists and clinicians has arisen due to the lack of a standardised definition of functioning and non-functioning tumours, as pointed out by Halfdanarson *et al.* Although non-functioning tumours are characterised by the lack of a clinical syndrome, they might secrete hormonal peptides as well, but only those tumours leading to clinical symptoms are referred to as functioning. For example, increased blood levels of pancreatic polypeptide or neurotensin can be found in NF-PNETs. Warner *et al.* already reported that plasma hormone levels do not always correlate with the presence of a clinical syndrome. For example, in case of the Zollinger-Ellison syndrome, fasting serum gastrin levels may be non-diagnostic (i.e., <1000 ng/l), or symptoms might be masked by the use of proton pump inhibitors or histamin receptor antagonists, or pernicious anaemia. Furthermore, it is reported that the hormonal secretion by the tumour is not always reflected in immunohistochemical staining for this hormone at pathology.

For a standardised approach, we recommend that the clinical diagnosis is superior to the pathological observations concerning the designation of the tumour as ‘functioning’ or ‘non-functioning’. In other words, in the absence of immunohistochemical positivity for a certain hormone in combination with increased serum levels of that particular hormone and/or the presence of a clinical syndrome, the tumour should be defined as ‘functioning’. In the opposite situation, i.e., a positive staining at pathology, but absence of increased serum levels and/or a clinical syndrome, the clinical presentation should be decisive, and the tumour should be defined as ‘non-functioning’.

Next, the existence of ‘benign’ GEP-NETs is disputed. Whereas the majority of GEP-NETs are considered to be malignant, insulinomas and appendiceal carcinoids are not. However, we believe that all GEP-NETs have malignant potential, and that early diagnosis of these tumours, because of the symptoms they cause, leads to the assumption that they are benign. Namely tumour size and/or invasion, and the presence of metastases, all characteristics which can
be ‘prevented’ by early detection, lead a tumour to being referred to as malignant.\textsuperscript{17-20} The fact that the majority of NF-NETs have a poor prognosis underlines that absence of clinical symptoms leads to a delay in diagnosis and a consequently more progressed tumour.

Another difficulty in diagnosing GEP-NETs arises as these tumours show a relatively high frequency of ‘ectopic occurrence’. For example, gastrinomas, which are usually located in the pancreaticoduodenal region and lymph nodes, have been reported on ectopic locations such as ovaries, biliary tract, kidneys, stomach and liver.\textsuperscript{44} Recently, we reported on a patient with recurrent hepatic metastases of occult primaries. Furthermore, GEP-NETs have been reported in rare locations such as the oesophagus, gallbladder and biliary ducts, Meckel’s diverticulum, ampulla of Vater, genital tract and skin.\textsuperscript{6,26} Lack of awareness that neuroendocrine lesions can also occur in bones is also important.\textsuperscript{45} Osteolytic bone lesions are not uncommon in patients with GEP-NETs, mainly gastrinomas and PNETs.\textsuperscript{46-48} The presence of a simultaneous second primary or metastatic malignancy must be thoroughly examined, as several case reports describe the existence of a second tumour synchronous with a carcinoid lesion.\textsuperscript{45,52} For example, gastrointestinal stromal tumours (GIST) are frequently seen in combination with (gastric) carcinoids.\textsuperscript{29,31} Furthermore, patients suffering from hereditary syndromes such as MEN-1, vHLD, neurofibromatosis type 1 or tuberous sclerosis, are at increased risk for a GEP-NET. Therefore, alertness for synchronous (neuroendocrine) tumours among clinicians is advocated. Furthermore, members from hereditary GEP-NET disorder families should be checked for such tumours, preferably by genetic counselling and, if possible, DNA profile, or by measurement of markers for these or associated tumours.

**RECENT DEVELOPMENTS IN THE DIAGNOSIS OF GEP-NETS**

As CgA is produced by all types of neuroendocrine cells, it serves as a highly sensitive neuroendocrine cell marker.\textsuperscript{14,15} In 2006, Kidd \textit{et al.} demonstrated that also CgA mRNA and protein levels were useful in the detection of gastrointestinal carcinoids and metastases.\textsuperscript{35} Recently, Modlin \textit{et al.} showed that measurement of circulating mRNA of CgA (and other markers such as Tph1 and NSE) provides a promising new diagnostic method for NETs.\textsuperscript{34} Next to CgA, several studies into other markers have been reported. In particular, investigators are interested to find markers which can discriminate between the diverse GEP-NET subtypes. Long \textit{et al.} demonstrated that PAX8 might be a useful immunohistochemical marker in the discrimination of pancreatic and ileal NETs, as the latter lack expression of this transcription factor.\textsuperscript{35} However, Hosoda \textit{et al.} found that immunohistochemistry on endoscopic ultrasound (US) biopsy specimens using a selected panel of markers, including CK-7, CDX-2, synaptophysin, CgA, and the KRAS mutational status, could be used to discriminate endocrine tumours from two other major types of pancreatic cancers (i.e., invasive ductal carcinoma and acinar cell carcinoma).\textsuperscript{36} A comparable study was performed by Burford \textit{et al.}, who found that strong immunohistochemical expression for E-cadherin and B-catenin were characteristic for PNETs, and could be used to discriminate from solid pseudopapillary neoplasm, in which staining is absent.\textsuperscript{37} Another selected panel, including CDX-2, NESP-55, TTF-1 and PDX-1, was described to be useful to discriminate between metastatic NETs of pancreatic, gastrointestinal and pulmonary origin, in a study by Srivastava \textit{et al.}\textsuperscript{36} In contrast, Fendrich \textit{et al.} found that PDX-1 expression was present in pancreatic but not duodenal gastrinomas, and PDX-1 expression in combination with Shh and PP expression in resected metastases might aid to locate undetected or occult primary gastrinomas.\textsuperscript{39} However, all the above-mentioned studies are non-conclusive, and further research and validation studies are needed before these diagnostic tools can be used in practice. Based on a literature review and analysis of the utility of plasma/serum CgA measurements in NETs, Modlin \textit{et al.} concluded that CgA still serves as the most specific (86%) and sensitive (68%) biomarker in plasma/serum to diagnose NETs that is currently available.\textsuperscript{40} The improvement of imaging techniques is one of the most probable explanations for the incidence increase of GEP-NETs. For example, in a study by Ishikawa \textit{et al.}, endoscopic US combined with contrast enhancement showed the best results in the preoperative localisation of PNETs in comparison with other imaging techniques, such as CT and US.\textsuperscript{41} Prasad \textit{et al.} reported that occult primary NETs could be detected by PET/CT using 68Ga-DOTA-NOC receptor in 59% of patients with confirmed NETs on biopsies from metastatic lesions, which was approximately three times higher than with CT alone.\textsuperscript{42} Also, research is ongoing in the field of genetic and molecular pathology. Previously, three detailed review articles
**Figure 2. Diagnostic algorithm for neuroendocrine tumours of the gastroenteropancreatic tract (GEP-NETs)**

### 1. CLINICAL DIAGNOSIS

1. **Detailed personal history and physical examination**
   - See table 1 for an overview of symptoms related to the various types of GEP-NETs.

2. **Determine localisation if possible, using:**
   - EUS or endoscopy in combination with CT scan or MRI scan
   - Somatostatin receptor scintigraphy or Octreoscan
     - Positive imaging: Continue with 3
     - Negative imaging: thorough search for occult tumours at unusual locations, continue with 3

3. **Measure plasma or serum CgA levels**
   - To verify the neuroendocrine nature of tumour

4. **Measure hormone levels in serum**
   - To detect possible peptide production by the tumour in order to define the tumour as ‘functioning’ or ‘non-functioning’.
   - *Note: Only define a tumour as a ‘carcinoid’ in case of increased serotonin serum levels and/or urinary 5-HIAA elevations, and/or the presence of the classical ‘carcinoid syndrome’ (see table 1).*

5. **Confirm diagnosis with a specific diagnostic test**
   - Positive test: Diagnosis confirmed, continue with II
   - Negative test: consider non-functioning tumour and/or differential diagnosis, continue with II

6. **Investigate the presence of a hereditary syndrome**
   - Detailed family history
   - Investigation for associated tumours and/or lesions
   - Gene testing
   - *Note: Consider the presence of synchronous tumours in case of gastric carcinoids (GISTs) or the presence of a hereditary syndrome.*

### II. PATHOLOGICAL DIAGNOSIS

1. **Immunostaining**
   - Staining for general neuroendocrine markers including chromogranin A, synaptophysin, NSE, keratin and Grimelius, to determine the neuroendocrine nature of the tumour.
   - *Note: For the definition of a neuroendocrine tumour, at least one of above-mentioned general neuroendocrine markers should show a positive staining.*
   - In case of a clinical (diagnosis or suspicion for) functioning tumour; Stain for specific hormones including serotonin, gastrin, insulin, glucagon, somatostatin, and/or VIP
   - *Note: Be aware that, also in case of a clinical functioning tumour, immunohistochemical staining for the particular hormone can be absent. Immunohistochemical staining should aid in determining the diagnosis, and determine the actual diagnosis.*

2. **Determine WHO classification**
   - Determination of proliferation index by Ki67 or MIBG1
   - Determination of mitotic count
   - Investigate tumour characteristics:
     - size
     - histological pattern
     - relation to other structures/invasion
     - angioinvasion
     - metastases
   - *Note: Define the tumour as NET or NEC, not carcinoid. The term carcinoid should only be designated (by clinicians) to tumours with serotonin production and/or in the presence of the classical carcinoid syndrome (table 1).*

3. **Determine TNM stage**
   - Determine tumour localisation
   - Determine tumour size
   - Determine invasion of the tumour into surrounding organs/structures
   - Determine the presence of lymph node metastases
   - Determine the presence of distant metastases

---

EUS = endoscopic ultrasound; CT = computerised tomography; MRI = magnetic resonance imaging; 5-HIAA = hydroxyindoleacetic acid; NSE = neuron specific enolase; VIP = vasoactive intestinal peptide; WHO = World Health Organisation; NET = neuroendocrine tumour; NEC = neuroendocrine carcinoma; TNM = tumour node metastasis staging system.
that describe recent advances in the molecular genetics of sporadic and familial GEP-NETs, were reported.\(^{3-4,44}\) Therefore, this review will not discuss this subject in detail.

**DIAGNOSTIC ALGORITHM**

The algorithm comprises a clinical and a pathological part. Although the pathological evaluation is important in the diagnosis, the clinical presentation largely determines the definition of a NET. However, we advocate an interdisciplinary cooperation between clinicians and pathologists in the diagnostic approach of GEP-NETs. Although research into specific biomarkers to detect GEP-NETs is ongoing, studies are still inconclusive. Therefore, we recommend CgA as a highly specific and sensitive neuroendocrine marker in the diagnosis of NETs. CgA measurement in plasma/serum, and immunostaining for this marker on biopsy or surgical specimens, should be performed routinely by clinicians and pathologists, respectively, in order to adequately diagnose (or exclude) a NET.

Imaging techniques to detect NETs are improving. The use of various imaging tools combined is advocated. In specialised centres, relatively new imaging modalities including PET scan can be used in the localisation of a NET. Repeatedly negative imaging results in detecting a primary NET should raise a physician’s suspicion for an ectopically localised NET. Furthermore, the presence of a secondary tumour should be investigated, in particular when a hereditary syndrome is present. For standardised documentation and in order to determine the therapeutic approach, tumours should be categorised according the WHO and TNM classification (figure 2).

**CONCLUSION**

GEP-NETs compose a complex and heterogeneous tumour entity, which forms a diagnostic challenge to physicians. In this review, we aimed to provide a clear overview of current diagnostic procedures and common pitfalls for GEP-NETs. Taking some recent diagnostic developments into account, we propose a diagnostic algorithm for GEP-NETs, to generate a more standardised diagnostic approach, facilitate the diagnosis, and eventually improve the early detection of these tumours.

**AUTHORS NOTE**

These data were presented at the Meeting of the ‘Nederlandse Vereniging van Gastro-enterologie (NvGE)’ 19 March 2010, Veldhoven, the Netherlands.
