A 23-year-old Asian man presented with a one-year history of intermittent cramping abdominal pain, followed by nausea and vomiting. At presentation, symptoms occurred two to three times a day and lasted for a few minutes to half an hour. Neither constipation nor diarrhoea or bloody stools were present and his weight was stable. Past medical history revealed a recent diagnosis of iron-deficiency anaemia for which he received iron supplements.

On physical examination the abdomen was soft with normal bowel sounds and no tenderness. Laboratory investigations showed microcytic anaemia (haemoglobin 7.7 g/dl) and no other abnormalities. Previous upper and lower endoscopy were unremarkable, with the exception of a mild non-specific gastritis for which he had been taking a proton-pomp inhibitor for two months. Abdominal computed tomography demonstrated a thickened small bowel wall within a proximal jejunum loop (figure 1) as a target-shape lesion in the axial plane (figure 2).

WHAT IS YOUR DIAGNOSIS?

See page 434 for the answer to this photo quiz.
**DIAGNOSIS**

Clinical history and radiological findings suggested an enterointeric intussusception. Surgical intervention showed invagination on a Meckel's diverticulum (Figure 3) and enlarged mesenteric lymph nodes around it. Diverticulectomy was performed and histopathological examination revealed inflammation and ulcerations. The postoperative course was uneventful and after eight weeks the patient was asymptomatic.

Intussusception represents a rare form of bowel obstruction in adults, accounting for 1-5% of intestinal obstructions. It is defined as the telescoping of a proximal segment of the gastrointestinal tract into the lumen of the adjacent distal segment. According to its location, intussusception can be classified into entero-enteric, if confined to the small bowel, colo-colic, involving the large bowel and ileo-colic, defined as prolapse of the terminal ileum within the ascending colon. It can also be classified by aetiology in benign, malignant or idiopathic. Small bowel intussusception in adults is mostly secondary to intra-luminal pathologies: neoplasms, inflammatory lesions and, rarely, Meckel's diverticula.

Meckel's diverticulum is the most common congenital malformation of the gastrointestinal tract (estimated prevalence 2-4%) and it results from incomplete obliteration of the vitello-intestinal duct. Meckel's diverticula are often discovered incidentally, especially in adults during abdominal exploration.

In this case, prophylactic diverticulectomy remains controversial. Park et al. recommend resection if there is a risk of a Meckel's diverticulum becoming symptomatic (i.e. age < 50 years, male sex, length of the Meckel's diverticulum > 2 cm and detection of abnormal features inside the diverticulum). Conversely, Zani et al. suggest a conservative approach, since resection would unnecessarily expose patients to a higher risk of postoperative complications. Currently, the recommendations are based on authors' experience and single-centre series, and little is known about long-term complications of incidental Meckel's diverticula left in situ.

Whether risk of cancer should affect management of asymptomatic Meckel's diverticula is unclear. Preoperative diagnosis of Meckel's diverticulum is challenging and features on abdominal CT may aid in establishing the diagnosis. Even if unusual, this condition should be considered in the differential diagnosis of abdominal pain and anaemia in young adults.
