ABSTRACT

Granulomatous infections are commonly associated with mycobacteria, brucellosis, actinomycosis, nocardiosis, spirochetes, and fungi. Rarely, granuloma formation is a host response to other bacterial infection. Osteomyelitis and osteitis that reactivate many years after the primary episode is a known phenomenon. A reactivation that presents as a granulomatous disease is rare. We present a case of reactivated osteitis due to Moraxella osloensis with consecutive granuloma formation.

KEYWORDS

Osteomyelitis, granulomatous disease, Moraxella osloensis

INTRODUCTION

The differential diagnosis for granulomatous disorders is broad. It includes infections, vasculitis, immunological aberrations, leukocyte oxidase defects, hypersensitivity reactions, host response to chemicals, or neoplasia. Granulomatous infections are commonly associated with mycobacteria, brucellosis, actinomycosis, nocardiosis, spirochetes, and fungi. Rarely, granuloma formation is a host response to other bacterial infection. Granuloma formation can also be triggered by osteomyelitis and osteitis. Here, we present a case of reactivated osteitis due to Moraxella osloensis that presented as granulomatous disease.

CASE REPORT

A 51-year-old woman presented with a progressive and slightly painful swelling arising in the soft tissue of her left forearm. She reported neither fever, nor weight loss, nor other systemic symptoms. Her history included a forearm fracture at the site of the current swelling, 46 years ago (i.e. in her early childhood). She recalled a surgical intervention, but did not remember the type of intervention, hospitalisations, medications, or follow-ups. Magnetic resonance imaging (MRI) showed a tumour surrounding the extensor tendon group, communicating with the cortical bone of the radius (figure 1A). Under suspicion of a malignant or myofibroblastic tumour, an incision biopsy was performed. The histopathological analysis did not reveal any signs of malignancy but the presence of granulomas. Culture for bacteria, Nocardia, mycobacteria, and fungi were negative. Thus, the 8 x 2 x 1.5 cm tumour was radically excised. The histopathological analysis again showed chronic granulomatous inflammation consisting of epithelioid histiocytes and giant cells surrounded by fibrosis, but without necrosis.

What was known on this topic?

Osteomyelitis that reactivates many years after the primary episode is a known phenomenon. Most reported cases are of Staphylococcus aureus as the causative pathogen.

What does this add?

This case is the first description of a reactivated osteitis due to M. osloensis triggering extensive granuloma formation. The clinical constellation may be misdiagnosed as musculoskeletal tumour or autoimmune disease. Molecular analyses may be required to identify difficult-to-detect microorganism.
Re-evaluation of the findings in view of a possible granulomatous disorder showed neither clinical nor laboratory signs of vasculitis (e.g. no lymphadenopathy, Wegener’s, polyarteritis nodosa, systemic lupus erythematosus) or immunological aberrations (e.g. Crohn’s diseases, primary biliary cirrhosis, hypogammaglobulinaemia). She denied contact with animals and chemicals. Biopsy sample cultures were negative for bacteria, Nocardia, mycobacteria, and fungi, as were multiple molecular analyses for mycobacteria. Serological tests for brucellosis, syphilis and Q fever were negative. The nitroblue tetrazolium dye test was not indicative of a chronic granulomatous disease. Because the finding was histopathologically consistent with an autoimmune disease (e.g. sarcoidosis), treatment with corticosteroids was initiated. After two months, the skin erythema, oedema, and warmth persisted. MRI was repeated and showed periosteal enhancement at the radius, indicative of persistent bone inflammation (figure 1B). When her history was re-evaluated again, the patient reported a feeling as if the disease was growing from her previous fracture site. Therefore, late reactivation of ostitis with consecutive granuloma formation was a differential diagnosis. Bone samples were reinvestigated with 16S-RNA polymerase chain reaction, revealing Moraxella osloensis. Corticosteroid treatment was tapered, and a three-month course with amoxicillin/clavulanate started. The further clinical course was favourable. At the one-year follow-up examination, the patient was symptom-free and MRI showed no evidence of inflammation (figure 1C).

**DISCUSSION**

Moraxella osloensis is an aerobic, gram-negative coccobacillus. Cases with bacteraemia, catheter-related infections, pneumonia, and meningitis have been reported, mostly in children or in immunocompromised hosts. However, M. osloensis can cause osteomyelitis and arthritis. In this patient, it was unclear whether the soft-tissue tumour caused bone erosions or the infection started primarily from the bone. Initially, the bone involvement was overlooked because of the impressive host reaction in the soft tissue. Also, whether or not posttraumatic bone infection occurred in her childhood remains unknown, because no disease documentation from that period was available. However, the patient’s history, the sum of all radiological findings, the lack of response to corticosteroids, the identification of a pathogen from a biopsy sample and the favourable course after antimicrobial treatment suggest late reactivation of posttraumatic osteomyelitis due to M. osloensis.

Osteomyelitis that reactivates many years after the primary episode is a known phenomenon. Most reported cases are of Staphylococcus aureus as the causative pathogen. However, virtually all microorganisms can cause osteomyelitis, and conceivably, reactivate at a later stage.
Sendi et al. Reactivated Moraxella osteitis presenting as granulomatous disease.

To the best of our knowledge, this is the first case of reactivation due to *M. osloensis*. Similar to previous cases, we were only able to identify the microorganism with 16S-RNA gene sequence analysis.

Chronic granulomatous inflammation is a rare but possible host reaction to osteitis. Skouby and Knudsen presented an osteomyelitis in a 3-year-old girl caused by *Kingella kingae*, formerly called *Moraxella kingie*. The histopathological finding in that case was consistent with eosinophilic granuloma. In our case, the patient was 5 years old at the time of the forearm fracture, and the reactivation of osteitis occurred 46 years later.

In conclusion, this case illustrates that the extent of granuloma formation can be significantly larger than the bone infection triggering it. The patient’s history pointed towards the diagnosis of reactivated osteitis. Finally, it shows that an otherwise unexplained histopathological finding of a chronic granulomatous inflammation should encourage the search for a causative pathogen, including those that are not typically associated with granulomatous infections, by all possible means.

**ACKNOWLEDGEMENTS**

We thank the Paediatric Haematology Laboratory of the University Children’s Hospital, Bern, Switzerland, for performing the nitroblue tetrazolium dye test.

**DISCLOSURES**

Consent

Written informed consent was obtained from the patient for publication of this case report and accompanying images.

This table is not exhaustive; MR = methicillin resistant; *P. acnes* = *Propionibacterium acnes*. The patient had recurrent osteomyelitis in this limb as a child from the age of 11. At the age of 17, he underwent resection of the distal right fibula. Reactivated osteomyelitis occurred in the regenerated fibula. Twenty-three years before presentation, the patient had undergone a craniotomy because of oligodendrogloma. No postoperative complications are described.
